**摘要:**研究了影响棉花钾吸收动力学参数的因素, 初步确定了钾吸收动力学方法在棉花上应用的条件, 比较了转基因抗虫棉新棉 99B 和常规棉中棉所 35 苗期的钾吸收特性。结果表明, 棉花钾吸收动力学参数受到苗龄、耗竭液中起始钾浓度及培养液中钾浓度的显著影响, 在苗龄较小(3~4 叶苗与 4~5 叶苗相比)、耗竭液中起始钾浓度较高(0.35 与 0.2 mmol · L<sup>-1</sup>相比)、培养液中钾浓度较高(2.0 与 0.5 mmol · L<sup>-1</sup>相比)的情况下,  $K_m$ 、 $C_{min}$  均比较高, 而  $I_{max}$  在前两种条件下较高、在后一种条件下较低。在 5~6 叶期, 新棉 99B 的  $I_{max}$  显著降低于中棉所 35, 而  $K_m$ 、 $C_{min}$  显著高于后者(培养液中  $K^+$  为 0.5 mmol · L<sup>-1</sup>), 耗竭液中起始  $K^+$  为 0.2 mmol · L<sup>-1</sup>), 说明新棉 99B 吸收有限钾的能力低于中棉所 35。

**Abstract:** It has been a main problem in cotton production that transgenic insect-resistant cotton is prone to premature senescence induced by K<sup>+</sup> deficiency, which makes it necessary to study K<sup>+</sup> uptake characteristics and, on the basis of it, to screen cotton cultivars with high K<sup>+</sup> uptake efficiency. This experiment studied the factors influencing K<sup>+</sup> uptake kinetic parameters of cotton, preliminarily identified the conditions of K<sup>+</sup> uptake kinetic applied to cotton, and compared the K<sup>+</sup> uptake characteristics of transgenic insect-resistant cotton cultivar, DP99B, and conventional cotton cultivar, CCRI 35, at seedling stage. The results showed that K<sup>+</sup> uptake kinetic parameters were significantly affected by seedling stage, initial K<sup>+</sup> concentration in depleting solution and K<sup>+</sup> concentration in culturing solution. Higher  $K_m$  and  $C_{min}$  resulted from younger seedling (3~4 vs. 4~5 leaf stage), higher initial K<sup>+</sup> concentration in culturing solution (0.35 vs. 0.2 mmol · L<sup>-1</sup>) and higher K<sup>+</sup> concentration in culturing solution (2.0 vs. 0.5 mmol · L<sup>-1</sup>), but higher  $I_{max}$  was produced under the two former conditions, and lower  $I_{max}$  came into being under the last situation. Compared with CCRI 35, DP99B had significantly lower  $I_{max}$  and higher  $K_m$  and  $C_{min}$  (0.5 mmol · L<sup>-1</sup> K<sup>+</sup> in culturing solution and 0.2 mmol · L<sup>-1</sup> initial K<sup>+</sup> in depleting solution) at 5~6 leaf stage, which indicated that the ability of DP99B to uptake limited K<sup>+</sup> was weaker than that of CCRI 35.

**Key words:** cotton; K<sup>+</sup>; uptake kinetics

## 1 Introduction

Since enzymatic reaction kinetics, by using *in vitro* root and radio-labeled rubidium<sup>[1]</sup> and/or *in vivo* root and non-radio-labeled potassium, named 'ion depletion method'<sup>[2]</sup>, was used to study potassium uptake of plant roots, a lot of studies have been carried out, including differences of intra-species and inter-species in K<sup>+</sup> uptake parameters I<sub>max</sub> (K<sup>+</sup> maximum uptake rate), K<sub>m</sub> (K<sup>+</sup> concentration in solution where K uptake rate was half of I<sub>max</sub>) and C<sub>min</sub> (where K influx equaled efflux)<sup>[3]</sup>, effects of seedling age<sup>[4]</sup>, internal K<sup>+</sup> content of seedling<sup>[5,6]</sup> and external environments<sup>[7]</sup> etc. on I<sub>max</sub>, K<sub>m</sub> and C<sub>min</sub>. I<sub>max</sub> represented maximum absorbing rate, which mattered when K<sup>+</sup> supply was abundant. K<sub>m</sub> represented competitive capacity of plant for limited K<sup>+</sup> source, which meant that the lower K<sub>m</sub> was, the stronger the competitiveness for K<sup>+</sup> was. C<sub>min</sub> was the minimum K<sup>+</sup> concentration below which K<sup>+</sup> couldn't be absorbed by root. When K<sup>+</sup> available in medium was limited, K<sub>m</sub> and C<sub>min</sub> greatly mattered. It has showed that I<sub>max</sub>, K<sub>m</sub> and C<sub>min</sub> varied in a wide range among varieties and species, and these K<sup>+</sup> uptake kinetic parameters could be effective tools to select crop varieties with high potassium efficiency for breeder and growers<sup>[8]</sup>.

Cotton had less root density than other crops<sup>[9]</sup>, which determined its relatively low K<sup>+</sup> uptake efficiency. Recently, premature senescence induced by potassium deficiency frequently happened to cotton, especially to transgenic insect-resistant cotton. Therefore, it was necessary to study the mechanisms of K<sup>+</sup> uptake of cotton. But up to now, few studies of K<sup>+</sup> uptake kinetics of cotton were found.

The objectives of this experiment were to investigate the effects of seedling age, initial K<sup>+</sup> concentration in the depleting solution and K<sup>+</sup> concentration in culturing solution, on the K<sup>+</sup> uptake kinetic parameters, based on that, to analyze the differences of K<sup>+</sup> uptake kinetic charac-

teristics between conventional variety CCRI 35 and transgenic insect-resistant cotton DP99B and to identify the conditions of K<sup>+</sup> uptake kinetic applied to cotton.

## 2 Materials and methods

### 2.1 Solution culture

The experiments were conducted in a growth chamber at 30°C day/25°C night, 10 h light/14 h dark condition using transgenic insect-resistant cotton DP99B and conventional variety CCRI 35. Photo-radiation at the canopy was 450 μmol · m<sup>-2</sup> · s<sup>-1</sup>. The seeds were surface sterilized by 9% H<sub>2</sub>O<sub>2</sub>, germinated and emerged in 1/4 modified Hoagland's solution described below without K<sup>+</sup>. Five-day-old seedlings were carefully transferred into 35 × 27 × 12 cm<sup>3</sup> pots rounded with aluminum foil. The pots were loaded with a modified Hoagland's solution, which contained 2.5 mmol · L<sup>-1</sup> Ca(NO<sub>3</sub>)<sub>2</sub>, 1 mmol · L<sup>-1</sup> MgSO<sub>4</sub>, 0.5 mmol · L<sup>-1</sup> (NH<sub>4</sub>)<sub>2</sub>H<sub>2</sub>PO<sub>4</sub>, 2 × 10<sup>-4</sup> mmol · L<sup>-1</sup> CuSO<sub>4</sub>, 1 × 10<sup>-3</sup> mmol · L<sup>-1</sup> ZnSO<sub>4</sub>, 0.1 mmol · L<sup>-1</sup> EDTA Fe Na, 2 × 10<sup>-2</sup> mmol · L<sup>-1</sup> H<sub>3</sub>BO<sub>3</sub>, 5 × 10<sup>-6</sup> mmol · L<sup>-1</sup> (NH<sub>4</sub>)<sub>6</sub>Mo<sub>7</sub>O<sub>24</sub>, 1 × 10<sup>-3</sup> mmol · L<sup>-1</sup> MnSO<sub>4</sub> and varied KCl for different K<sup>+</sup> treatments. All solutions were changed twice a week and de-ionized water was added daily to replace the water lost by evapo-transpiration. The pH was maintained close to 6.5 by adding H<sub>2</sub>SO<sub>4</sub>. Air was bubbled into the nutrient solution by air pump to provide O<sub>2</sub> and mix solution homogeneously.

### 2.2 Determination of K<sup>+</sup> uptake kinetic parameters and K<sup>+</sup> content in root

K<sup>+</sup> uptake kinetic parameters were determined by using ion-depletion method<sup>[2]</sup>. Three uniform seedlings were selected as a unit, and put into 500 ml beakers loaded with 300 ml above described nutrient solution without K<sup>+</sup>, which was hereby defined as K<sup>+</sup> starvation of seedlings. After 48 hours, the seedlings were taken out from the solution. Their roots were

washed with  $0.5 \text{ mmol} \cdot \text{L}^{-1} \text{ CaSO}_4$  three times. Then the seedlings were again put into the beakers with 300 ml uptake solution (hereon called depleting solution) comprised of different initial KCl content and  $0.5 \text{ mmol} \cdot \text{L}^{-1} \text{ CaSO}_4$ , where  $\text{Ca}^{2+}$  can guarantee integrity of membranes and minimize ions efflux<sup>[10]</sup>. At 10~30 min intervals, 1.5 ml solution was taken out. At intervals of 30 minutes, 5 ml ionized water was added against evapo-transpiration. After some duration, the procedure was stopped. Seedlings were taken out and weighed for fresh root weight. Root was oven-dried at  $75^\circ\text{C}$ , grounded, and  $\text{K}^+$  was extracted from root with  $1 \text{ mmol} \cdot \text{L}^{-1}$  ammonium acetate ( $\text{pH} = 7.0$ ). Extracted  $\text{K}^+$  of root and  $\text{K}^+$  in taken-out solution were determined by atomic absorption spectroscopy (Varian SpectraAA). During depletion,  $\text{K}^+$  concentration in solution decreased as a binomial function of time, so  $I_{\max}$ ,  $K_m$  and  $C_{\min}$  were calculated according to the following formulae:

$$\text{Conc.} = A * t^2 + B * t + C$$

$$I = -d \text{ Conc.} / dt = -2 * A * t - B$$

$$I_{\max} = |B| * V / \text{FRW}$$

$$K_m = B^2 / 16A - B^2 / 4A + C$$

$$C_{\min} = B^2 / 4A - B^2 / 2A + C$$

Note: Conc.:  $\text{K}^+$  concentration in the depleting solution; t: time; A, B: coefficients; C: constant; I:  $\text{K}^+$  influx rate;  $I_{\max}$ : maximum influx rate;  $K_m$ ,  $C_{\min}$ :  $\text{K}^+$  concentration in the depleting solution where I was a half of  $I_{\max}$  and tended to zero, respectively; V: the volume of the depleting solution; FRW: fresh root weight.

### 2.3 Experiment designs and statistical analysis

In this experiment, effects of seedling age (sub-experiment 1),  $\text{K}^+$  concentration in culturing solution (sub-experiment 2) and initial  $\text{K}^+$  concentration in depleting solution (sub-experiment 3) on parameters of  $\text{K}^+$  uptake kinetics were investigated. Further,  $\text{K}^+$  uptake kinetic parameters of CCRI 35 and DP99B were compared (sub-experiment 4). At seedling age,  $\text{K}^+$  concentration in culturing solution and initial  $\text{K}^+$  concentration in depleting solution of each sub-experiment were detailed in table 1.

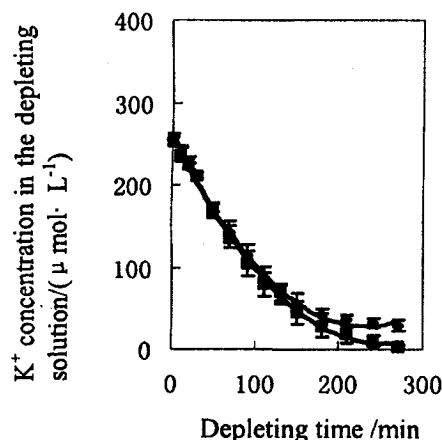

A completely randomized design with three

replications was used for each of four experiments. All data were subject to ANOVA test and means were compared using the Fisher's protected LSD ( $P < 0.05$ ).

## 3 Results

### 3.1 Factors influencing $\text{K}^+$ uptake kinetic parameters

**3.1.1 Seedling age.** When seedlings growing from 3-4 leaf to 4-5 leaf, fresh root weight increased by 70.8%,  $\text{K}^+$  concentration in root decreased by 19.1%, and  $I_{\max}$ ,  $K_m$  and  $C_{\min}$  decreased by 41.4%, 17.7% and 72.7%, respectively. The decrease of  $K_m$  and  $C_{\min}$  indicated the competitive uptake on limited  $\text{K}^+$ , which should result mainly from the decrease of  $\text{K}^+$  concentration in root (Table 2 and Figure 1).

Fig. 1  $\text{K}^+$  uptake kinetics curve of seedlings at different growth stages.

**3.1.2  $\text{K}^+$  concentration in the culturing solution.** Seedlings with  $2 \text{ mmol} \cdot \text{L}^{-1} \text{ K}^+$  had significantly 68% higher fresh root weight and 191.8% higher  $\text{K}^+$  concentration in root, on the other hand, had 40% lower  $I_{\max}$  and 55.9% higher  $K_m$  and 896% higher  $C_{\min}$ , compared with seedlings cultured with  $0.5 \text{ mmol} \cdot \text{L}^{-1} \text{ K}^+$  in solution. This indicated that the  $\text{K}^+$  uptake ability reduced as a result of  $\text{K}^+$  concentration increment in root (Table 2 and Figure 2), which was accordant with the above result.

Table 1 Seedling age,  $K^+$  concentration in culturing solution and initial  $K^+$  concentration in depleting solution of each sub-experiment

	seedling age true leaf	$K^+$ in culturing solution /( $mmol \cdot L^{-1}$ )	initial $K^+$ in depleting solution /( $mmol \cdot L^{-1}$ )
sub-experiment 1	3~4 and 4~5	0.5	0.25
sub-experiment 2	5~6	0.5 and 2.0	0.20
sub-experiment 3	5~6	0.5	0.20 and 0.35
sub-experiment 4	5~6	0.5	0.20

Fig. 2  $K^+$  uptake kinetics curve of seedlings cultured with different  $K^+$  concentration in culturing solution

3.1.3 Initial  $K^+$  concentrations in depleting solution. With seedlings cultured in same conditions, higher initial  $K^+$  concentration ( $0.35$  vs.  $0.2 mmol \cdot L^{-1}$ ) during depletion made  $K^+$  concentration in root,  $I_{max}$ ,  $K_m$  and  $C_{min}$  elevated significantly by 84.3%, 20.0%, 24.4% and

255.6%, respectively. This suggested that higher exterior  $K^+$  raised the initial rate and accumulation of  $K^+$  influx into root during depletion, which further inhibited the  $K^+$  uptake, and produced higher  $K_m$  and  $C_{min}$  (Table 2 and Figure 3).

	$I_{max}$ (FW)	$K_m$	$C_{min}$		
	$/\mu\text{mol} \cdot (\text{g} \cdot \text{min}^{-1})$	$/(\mu\text{mol} \cdot \text{L}^{-1})$	$/(\mu\text{mol} \cdot \text{L}^{-1})$	$/\%$	$/\text{g}$
CCRI 35	0.10A	40.32B	2.50B	1.47B	2.49A
DP99B	0.07B	61.72A	27.50A	1.96A	2.92A

Note: Values in each column followed the upper-case letters for comparison between two cultivars at  $P < 0.05$  by LSD test.

### 3.2 Comparisons of $K^+$ uptake kinetic characteristics between CCRI 35 and DP99B

Compared with transgenic insect-resistant cotton DP99B, conventional variety CCRI 35 had similar fresh root weight, 25% lower  $K^+$  concentration in root, but significantly 42.8% higher  $I_{max}$  and 34.7% lower  $K_m$  and 90.9% lower  $C_{min}$ . As mentioned above, lower  $K^+$  concentration in root maybe contributed to the higher  $I_{max}$  and lower  $K_m$  and lower  $C_{min}$  (Table 3 and Figure 4). Furthermore, this result implied that conventional variety CCRI 35 could use limited  $K^+$  more efficiently than transgenic insect-resistant cotton DP99B.

Diamond symbol (◆): DP99B; Foursquare symbol (■): CCRI35

## 4 Discussions

### 4.1 Conditions of $K^+$ uptake kinetics applied to cotton

In order to obtain desirable kinetic curve, it was necessary to get the absorption rate varied grad-

ually from rapidly to slowly. Factors influencing  $K^+$  uptake kinetic should contain seedling age, seedling number as a unit, volume and initial  $K^+$  concentration of depleting solution,  $K^+$  concentration in culturing solution (this resulted in  $K^+$  concentration variation in root) and certain starvation time (this guaranteed  $I_{max}$  available). The results of this experiment indicated that relatively appropriate  $K^+$  uptake kinetic curves of cotton was obtained with 3-6 leaf seedling under conditions as follows:  $450 \mu\text{mol} \cdot \text{m}^2 \cdot \text{s}^{-1}$  of photo-radiation, 0.5 or 2  $\text{mmol} \cdot \text{L}^{-1}$   $K^+$  of culturing solution, 48 hours of seedlings starvation, 3 plants as a unit, 300 ml  $K^+$  depleting solution with 0.2, 0.25 or 0.35  $\text{mmol} \cdot \text{L}^{-1}$  of initial  $K^+$ .

$K^+$  concentration in root decreased with seedling age, which might be a dilution of rapid root growth, a growth from  $0.79 \text{g} \cdot \text{plant}^{-1}$  at 3~4 leaf stage to  $1.35 \text{g} \cdot \text{plant}^{-1}$  at 4~5 leaf stage. But the difference of  $K^+$  concentration in root between two seedling stages couldn't completely account for the bigger differences in  $I_{max}$ ,  $K_m$  and  $C_{min}$ . They all significantly decreased with seedling growing, which didn't completely accord with the results from Peng [4], who suggested that there was a small reduction in  $I_{max}$  and a slow ascension in  $K_m$  with plant age increasing.

There was a positive correlation between increment of  $K^+$  influx and reduction of  $K^+$  concentration in roots [5, 6]. To some extent, internal  $K^+$  of root increased,  $K_m$  increased [6]. In this experiment, while  $K^+$  concentration in culturing solution increased from 0.5  $\text{mmol} \cdot \text{L}^{-1}$  to 2  $\text{mmol} \cdot \text{L}^{-1}$ , the fresh root weight and  $K^+$  concentration in root of seedlings got significantly enhanced, which led to significant increment of  $K_m$  and  $C_{min}$ , and significant decrease of  $I_{max}$ . It was manifested that  $K^+$  uptake

efficiency was regulated strongly by feed back of internal  $K^+$  of root.

With initial  $K^+$  enhanced from  $0.2 \text{ mmol} \cdot \text{L}^{-1}$  to  $0.35 \text{ mmol} \cdot \text{L}^{-1}$  during depletion,  $I_{\max}$  was improved significantly, while  $K_m$  and  $C_{\min}$  were increased significantly and strongly. Those changes may attribute partly to significant disparity of  $K^+$  concentration among seedlings in different initial  $K^+$  concentrations during depletion, which provided another evidence for the feed back regulation of internal  $K^+$  of root on  $K^+$  uptake.

Considering the  $K^+$  concentration in natural soil solution and obvious effects of higher initial  $K^+$  in depleting solution on  $K_m$  and  $C_{\min}$ , it may be appropriate to select cotton varieties with high potassium efficiency under the following conditions: 5~6 leaf seedlings,  $0.5 \text{ mmol} \cdot \text{L}^{-1} K^+$  in culturing solution and  $0.2 \text{ mmol} \cdot \text{L}^{-1}$  initial  $K^+$  in depleting solution.

#### 4.2 Comparison of $K^+$ uptake kinetic characteristics between CCRI 35 and DP99B

Taking seedlings grown in Hoagland's solution with  $0.5 \text{ mmol} \cdot \text{L}^{-1} K^+$  for comparisons, great gaps existed between CCRI 35 and DP99B in  $K^+$  uptake kinetic characteristics. Compared with Bt cotton DP99B, conventional variety CCRI 35, depending on its significantly lower  $K_m$  and  $C_{\min}$ , might have a competitive edge on using limited  $K^+$  source. But it is yet testified if susceptibility of premature senescence of DP99B was highly related to low  $K^+$  uptake efficiency in seedling stage. Although high internal  $K^+$  of root could affect  $I_{\max}$ ,  $K_m$  and  $C_{\min}$ ,  $0.49\%$  increment of  $K^+$  concentration in root from  $1.47\%$  (for CCRI 35) to  $1.96\%$  (for DP99B) could not sufficiently account for bigger disparity of  $K_m$  and  $C_{\min}$  between two varieties, which resulted from the facts that  $K^+$  uptake dynamic of different varieties may vary with seedling age, and appropriate initial  $K^+$  concentration during depletion for different varieties may be distinct.

#### 4.3 Evaluation and prospect of $K^+$ uptake kinetics suitable to cotton

$K^+$  uptake kinetics by root has played a great

role in selecting high  $K^+$  efficient species and varieties<sup>[8]</sup>, but few applications on cotton were found. Above results showed that  $K^+$  uptake kinetics may be suitable to select cotton varieties with high potassium efficiency, but it needs to investigate whether  $K^+$  uptake efficiency difference among cotton varieties in seedling stage could be applied to other growth and development stages, especially to maturation stage.
